The spectroscopic properties of Li₂O - Na₂O₃ - B₂O₃ glass containing different concentrations of MoO₃ (ranging from 0 to 1 mol %) were prepared by melt quenching and are studied. Spectroscopic (XRD, infrared, optical absorption spectra and EPR) properties of these glasses have been carried out. As the concentration of MoO₃ is increased especially beyond 0.4 mol %, the colour of the glasses increased, which is indicating the reduction of molybdenum ions from the Mo⁶⁺ state to the Mo⁵⁺ state. The Optical absorption Spectrum contains one broad absorption band around 695 nm is attributed to the excitation of Mo⁵⁺ (4d¹) ion. EPR studies reveal Molybdenum ions are expected to exist mainly in the Mo⁶⁺ state in the glass network. EPR, FTIR and Optical absorption spectra of paramagnetic ion in the above glasses reveal that the site symmetry of the transition metal ion is elongated octahedral.

Introduction:

The glasses containing transition metal ions came into prominence because of their notable spectroscopic properties and their suitability for fibre optic communications, luminescent solar energy concentrators (LSC) [1]. Among the many glasses, borate glasses have been known to be excellent host materials for transition metal oxides because of their glass forming nature compared to other conventional glass systems. Borate glasses are used as wave-guides, electro-optic switches, electro-optic modulators, magneto-optic materials, solid-state laser materials and non-linear optical parametric converters [2–4]. In addition, they are often used as dielectric and insulating materials and it is known that borate glass constitute a good shield against IR radiation [5]. In general B₂O₃ glasses have a property of showing minimum expansion due to the large amount of boric oxide which is of great importance in obtaining thermal durability. It also decreases the tendency for glass to devitrify or crystallize. B₂O₃ is a basic glass former because of its higher bond strength, lower cation size and smaller heat of fusion. The ions of molybdenum introduce high activity and selectivity in a series of oxidation reactions of practical importance in the glass matrices [6,7].

Molybdenum oxide belongs to the intermediate class of glass forming oxides. It does not readily form the glass but does so in the presence of the modifier with MoO₄. Molybdenum ions in the glasses have been the subject of many investigations due to their catalytic properties. Interesting studies are available on the environment of molybdenum ion in different inorganic glasses [8–13]. Mo–O bond in molybdenum hexavalent oxide is identified as significantly covalent. The Mo ion exist a stable valence state viz., MoV and MoVI in the glass network. Molybdenum ions act both as network formers as well as network modifiers depending upon their concentration and nature of the host network. Mo–O bond in molybdenum hexavalent oxide is identified as covalent. The Mo ion exists at least in two
stable valence states viz., Mo (V) and Mo (VI) in the glass network. Earlier EPR studies on the glasses containing molybdenum ions have identified the presence of octahedrally coordinated Mo (V) ions along with octahedral distortion approaching tetragons [14,15]. These ions act both as network formers as well as network modifiers depending upon their concentration and nature of the host network. The Mo^{6+} ions are expected to participate in the glass network with tetrahedral MoO_4^- structural units and may alternate with BO_4^- tetrahedral units. Most of the studies available on MoO_3 containing glasses are on the understanding of their structure by spectroscopic investigations [16, 17] and ionic conductivity studies [18].

In the present work the influence of MoO_3 in varying concentrations, on resonance and absorption properties of lithium-sodium-borate glasses are studied. Optical band gaps for both direct and indirect transitions and Urbach energies were calculated and those glasses were also characterized by XRD and FTIR studies.

**Experimental:**
The glasses of the system 20Li_2O – 10 Na_2O – (70-X) B_2O_3 (X=MoO_3 ) have been prepared by melt quenching technique varying the concentration of molybdenum ranging from 0.2-1.0(mol%). The raw materials used were analytical pure (99.5%). Appropriate amounts of weighed chemicals Na_2O, Li_2O, B_2O_3, MoO_3 were grounded thoroughly in a mortar to produce homogeneous mixture. This homogenized mixture was then placed in porcelain crucibles and melted in an electrical furnace at 870-920℃ for half an hour until a bubble free liquid was formed . The melt was then quenched to room temperature by pouring it on a plane brass plate and pressing it with another brass plate. Finally the vitreous samples were annealed for 3 hrs at 423K to relieve residual internal stress and slowly cooled to room temperature. The glasses so obtained were brown in colour with good optical quality and transparency. Details of experimental procedure and calculations are similar to the earlier work [14].

**Results and Discussion:**

**X-ray diffraction:**
X-ray diffraction technique has been widely used to characterize inorganic glasses as it readily detects crystals in glassy matrix.

![Figure 1](image1.png)

**Figure 1:** The XRD patterns of molybdenum doped LNB glass system

Figure 1 represents the XRD patterns for Li_2O- Na_2O -B_2O_3; MoO_3 compositions of glasses and as can be seen diffraction patterns of all the prepared glasses do not demonstrate any detectable crystalline peaks indicating amorphous or non-crystalline nature of the samples.

**Infrared Spectra:**
The prominent IR bands shown in Fig. 2 are observed for Li_2O- Na_2O -B_2O_3; MoO_3 glasses and these bands are effectively influenced by the molybdenum content in the glasses network. The molybdenum free glasses exhibited in the regions 1300-1450 cm^{-1}, 1100-1200 cm^{-1}. These bands are identified as stretching relaxations of B-O bonds of the trigonal BO_3 units. Broad absorption bands are observed at 1050-850cm^{-1} and 800-700 cm^{-1}; these bands are
identified due to stretching vibrations of the [BO$_4$] units. When molybdenum is added, two new bands attributed to $\nu_1$ and $\nu_3$ vibrational modes of [MoO$_4$]$^2-$ tetrahedral units and [MoO$_6$]$^{6-}$ was located at about 810 and 550 cm$^{-1}$. The bands at 448 and 548 cm$^{-1}$ were specific to the vibrations of Li–O bonds in Li$_2$O octahedral units. The summary of various band position of Li$_2$O- Na$_2$O -B$_2$O$_3$: MoO$_3$ is presented in the Table II.

\end{table}

Absorption Spectra:-
The Optical absorption spectra of the Li$_2$O- Na$_2$O -B$_2$O$_3$: MoO$_3$ glasses are recorded at room temperature in the wavelength range 400nm-1400nm The Optical absorption spectrum of molybdenum doped lithium sodium borate glass (with x=0.6 mol %) is shown in the Fig. 3. The absorption edge is observed to shift towards higher wavelength side.

\end{figure}
Figure 3:- Optical absorption spectrum of Lithium-Sodium-Borate glass system containing 0.6 mol % of Mo$^{6+}$ ions at room temperature

The spectrum of MoO$_3$ free glasses does not exhibit any absorption band. But small amount of molybdenum is added to glasses matrix shows a broad optical absorption band at about 695 nm (for $x=0.6\%$). The intensity of this band was observed to increase gradually as the concentration of MoO$_3$ increased. From the observed absorption edges (fig3a,fig3b,fig3c) direct, indirect band and Urbach energy gap are evaluated and are presented in Table II. The values of direct and indirect band gap energies, decreases from M0.2 to M1.0.

EPR Spectra:
EPR spectra of $\text{Li}_2\text{O}$- $\text{Na}_2\text{O}$- $\text{B}_2\text{O}_3$: $\text{MoO}_3$ glasses doped with different concentrations of $\text{MoO}_3$ were recorded at room temperature. The EPR spectra of these glasses consist of a main central line surrounded by less intense satellites. The EPR spectra of the glasses recorded at room temperature exhibit signals consisting of a central line surrounded by smaller peaks at about $g_{||}=1.811$ and $g_{\perp}=1.956$ for M0.6 glass system and is shown in Fig.4.
The EPR spectra obtained for the molybdenum ions in the titled glasses are similar to those obtained for various other glass systems [20–22]. The spectra shown in Fig. 4 can best be analyzed using a spin-Hamiltonian of the form: 
\[ H = \beta S g B + S A I \]
where the symbols have their usual meaning. It contains the electronic Zeeman term (\( \beta \) is the bohr magneton, \( S = 1/2 \) the electron spin, \( g \) is the \( g \) tensor and \( B \) is the applied field), perturbed by the hyperfine coupling term between the unpaired electron and the nuclear spin \( I \) of molybdenum ion, \( A \) being the hyperfine structure tensor. The central line arises from even molybdenum isotopes (\( I = 0 \)), while the smaller lines correspond to the hyperfine structure from odd \( ^{95}\text{Mo} \) and \( ^{97}\text{Mo} \) isotopes (\( I =5/2 \)). The nuclear magnetic moments of \( ^{95}\text{Mo} \) and \( ^{97}\text{Mo} \) being close, so the isotope splitting is not resolved in the EPR spectra. It can be assumed that \( \text{Mo}^{5+} \) ions in the glasses studied has an octahedral coordination with a weak axial distortion. An octahedral site with a tetragonal compression usually shows of and \( g_\parallel < g_\perp < g_e (=2.0023) (=2.0023) \) [23].It is found that the values obtained for the glasses under study, are more close to those of the molybdenyl ions. The values of \( g_\parallel \) and \( g_\perp \) from these spectra have been evaluated and presented in Table III. Further, the \( g \) values obtained for these glasses are found to be consistent with the reported values for many other glass systems containing molybdenum ions. \( A_\parallel \) and \( A_\perp \) are the parallel and perpendicular components of the hyperfine tensor \( A \). It is observed that the intensity of the resonance signal increases with increase in the concentration of \( \text{MoO}_3 \).

The EPR transition can be explained as because of decrease of the effective charge of the surrounding oxygen ligands, there is decrease in their electron donating ability (\( \sigma \)-bonds), hence the charge of the central molybdenum remains high. Therefore, this induces the promotion of strong \( \pi \)-bond with the two axial oxygens of the compressed octahedron hence axially distorted environment is developed. By this the \( \text{Mo(V)} \) is strongly displaced in its octahedron so that it adopts a pyramidal configuration \( \text{MoO}_5 \) with a very short \( \text{Mo-O} \) distance, which would correspond to the molybdenyl ion [24].
Conclusions:
The conclusions drawn from analysis of the results of the various properties of Li$_2$O–Na$_2$O-B$_2$O$_3$: MoO$_3$ glasses reported in this study are as follows:

- XRD spectra revealed amorphous of the sample.
- The FTIR Spectral studies indicate that the molybdenum ions occupy tetrahedral positions in higher concentrations.
- The Optical absorption Spectra of Li$_2$O–Na$_2$O-B$_2$O$_3$: MoO$_3$ glasses exhibits bands associated with transitions at Mo$^{5+}$ ions, indicating that the molybdenum ions is in pentavalent state, in addition to tetravalent and hexavalent states respectively in these glass samples.
- The EPR Spectra of these glasses exhibit a signal consisting of a triplet separated by smaller satellites. The signal has been identified as arising from tetragonally distorted octahedral positions of Mo$^{5+}$ ions.
