Statistical analysis, conductive fissures, cumulative percentages of linear discharges, Divo-Guitry.

Abstract

5 The nearby study analyses the solid waste management in Tamil Nadu. Solid waste comprised all the wastes arising from human and animal activities that are normally solid and that are discarded useless or unwanted. The increasing difficulty in managing wastes in different states in Tamil Nadu. On the basis of the results, it was recommended to increase public awareness through enlightenment campaign against danger of indiscriminate dumping of wastes as they affect human health.

1 Introduction: -

Hard rocks or crystalline rocks (i.e., plutonic and metamorphic rocks) constitute the basement of all continents and are particularly exposed at the surface in the large shields of Africa, India, North and South America, Australia and Europe (Lachassagne et al. 2021). These rocks become aquifers only when they are affected by ruptures (cracks, fractures). The latter concentrates most of the water resources of the basement aquifers (Tagnon et al., 2018). These aquifers are of strategic importance, particularly in rural areas and regions where surface water resources remain limited. Indeed, although the discharges from these aquifers are relatively modest, they regularly provide drinking water relatively closer to the population and protected from pollution and climatic hazards. However, these aquifers are complex (Kouamé, 1999) and are therefore the subject of numerous studies (Biémi, 1992; Savané, 1997; Kouamé, 1999; Lachassagne et al., 2000; Holland and Witthüser, 2011; DesRoches et al., 2014; Douagui et al., 2019; Lachassagne et al. 2021; Akpan et al., 2023; Walraevens et al., 2025). This complexity is explained by the fact that, in the hard rocks, the levels of weathering and fracturing are variable. This implies a discontinuous spatial distribution of aquifer's recharge, storage capacity and permeability. Thus, it is relatively difficult to predict the flow rates to be extracted from the hard rock aquifers and the path of the water flowing there. Drinking water supply campaigns from boreholes are therefore marked by uncertainties and the failure rates noted there often exceed 70 % (Tagnon et al., 2016, 2018 ; Courtois et al. 2010; Vouillamoz et al. 2014; Alle et al. 2018). These failures are due to the combination of several factors, including poor knowledge of the complex hydrogeological environment of hard rock aquifers. They represent significant economic losses in investment in drinking water supply projects. For example, currently in Côte d'Ivoire, the average cost per linear meter dug in the hard rock areas can be estimated at 25,000 CFA francs (or £38.11). Thus, if a drinking water supply project drills 100 boreholes, each reaching a depth of 100 m, a failure rate of 40 % will correspond to a loss of 100,000,000 CFA francs (or £152,449.02) on the investment cost.

Several studies, most of which used a multidisciplinary approach, have advanced the level of knowledge on hard rock aquifers. Relatively recent work (Lachassagne et al., 2009, 2011, 2015, 2021; Cho et al., 2002; Wyns et al., 2004; Maréchal et al., 2003; Dewandel et al., 2006, 2011) has widely popularized within the scientific community the concept of "aquifer generated by the weathering process". This work showed that it is the weathering process, not tectonic movements and lithostatic decompression, that is the key factor that transforms hard rock into an environment capable of containing exploitable groundwater. This work argued that the weathering process begins with the swelling of certain minerals such as biotite. From there, cracking and fracturing begin, the outcome of which is dictated by the evolution of the weathering process at the rock scale. In the weathering profile that

develops, the hydrodynamic parameters (transmissivity, storage) are linked to the lithology and geometry of the different layers constituting the weathering profile (Courtois et al., 2010).

The conceptual model of the hard rock aquifers therefore suggests a quasi-continuity of hydrodynamic properties, at the scale of a given rock type. This approach makes it possible to regionalize the hydrodynamic properties of these aquifers and gives rise to practical applications such as the sustainable management of water resources at the scale of watersheds, through multi-layer mathematical modeling tools (Lachassagne et al., 2009, 2011, 2015, 2021).

The statistical analysis of borehole data within the concept of aquifer generated by the weathering process, as developed by Courtois et al. (2010), is of great interest, particularly in rural areas of developing countries. In these countries, adequate funding for multidisciplinary hydrogeological exploration and water well drilling is often unavailable, especially in rural areas. Thus, for localities where a database of previously drilled boreholes and regional geological maps exist, statistical processing of borehole data, from the perspective of the aquifer concept generated by the deep rock weathering process, provides valuable information on aquifer properties. This information could guide future drilling campaigns and be taken into account in the implementation of sustainable water resource management tools.

This study, which is applied to the Divo-Guitry area, statistically processes drilling data, within the concept of aquifer generated by the weathering process. Like the entire southern forest part of Côte d'Ivoire, Divo-Guitry is a strategic area in the Ivorian economy. Indeed, with a dense population, Divo-Guitry is high agricultural production area, with, in addition, rapidly expanding mining activities. The pressure of these activities on water resources is increasing. All of this appears to be exacerbated by the effects of climate change. This area needs to address its growing water needs and develop a sustainable water resource management tool (Tagnon et al., 2016, 2018, 2020). The objective of the study is to assess the geometric and hydrodynamic properties of the Divo-Guitry fractured hard rock aquifer to guide the location of future water wells. It identifies the specific hydrogeological parameters associated with each rock type, determines the most productive zones in the fractured layer, the average productivity of the aquifer, and establishes a spatial distribution of optimal well depths to drill. This work is a continuation of previous ones (Asemian et al., 2014; Kouamé et al., 2021; Aoulou et al., 2021; Bouatrin et al., 2022) conducted in different areas of Côte d'Ivoire and which adopted the same approach to statistically analysis drilling data. However, this study is notable for its statistical analysis, distinguishing three types of crystalline rocks (metatonalite, metagranite, and metagranodiorite) and providing a map of the optimal drilling depth.

The information obtained will be an important contribution to hydrogeological exploration and the development of a water resource management tool at the regional scale.

2. Methodology

2.1. Study area

Divo-Guitry area is in the southern part of Côte d'Ivoire, between longitudes 5 ° and 6 ° West and latitudes 5°27' and 6 °10' East (Figure 1).

Figure 1. Map presenting the study area and distribution of lithological formations

This area covers 144 km² and includes the localities of Zikisso, Lakota, Divo, Guitry, and Gbagbam. It is an area of dense and fast-growing population (over 3.8 % / year), practicing intense agricultural activities and where mining operations are expanding rapidly (Tagnon et al., 2020). The climate consists of 4 seasons: long dry season from November to February; long rainy season from March to June; short dry season between July and August and finally, short rainy season from September to October.

Geomorphologically, the landscape is relatively flat, with elevation decreasing from 300 m above sea level (ASL) in the North-west (in Zikisso area), to 20 m ASL in the South-east (in Guitry area). Thus, following the arrangements of the geological formation bands, the thicknesses of the saprolites are generally greater on the biotite metagranite (MGR) than on the biotite metagranodiorite (MGDR), where they are also higher than on the metatonalite (MTR) (Tagnon, 2021).

The information about geology of the study area is mainly extracted from Delor et al. (1995). The geological formations belong to Paleoproterozoic (Geomines 1982; Delor et al., 1995) and consist of volcano-sedimentary rocks and intrusive rocks.

Volcano-sedimentary rocks are relatively small in extent across the study area. Two blocks, one in the northern part and the other in the southeastern part of the study area, are distinguished (Figure 1).

Intrusive rocks essentially cover the study area. These rocks consist of biotite metagranite (MGR), biotite and/or hornblende metagranodiorite (MGDR), and metatonalite (MTR). The MGR belt extends across the western part of the study area and includes the localities of Zikisso and Lakota. The MGDR is in the central part of the study area and borders the northern block of volcano-sedimentary rocks. The MTR belt, elongated NE-SW, extends between the MGDR and the northern block of volcano-sedimentary rocks on the one hand, and the eastern block of volcano-sedimentary rocks on the other (Figure 1).

2.2. Data

Digital geological maps and data from water boreholes were used for this study. The geological maps are from the square degrees of Grand-Lahou and Gagnoa and were provided by the geology department of Côte d'Ivoire. The water wells are distributed upon three types of lithology which are MGR, MGDR and MTR.

The database contains 275 boreholes, distributed across geological formations as follows: 33 on MGDR, 92 on MGR and 150 on MTR. Each borehole in the database is informed with the following informations: X, Y, and Z coordinates; geology; total depth; saprolite thickness; depth to static level; depth and discharge of inflows and instantaneous discharge (air lift flow measured at the end of the drilling by blowing air under pressure at the bottom of the well (Courtois et al., 2010)). All boreholes cross the saprolite horizon and capture the fissured layer.

2.3. Methods

The work consisted of analyzing data from boreholes dug on three types of intrusive geological formations: MGR, MGDR and MTR. The study was carried out on these three types of lithologies because they cover almost the entire study area and the data we have there has a heterogeneous distribution.

First, a statistical analysis was performed to determine the distribution of each borehole parameter. Next, the analysis focused on the variation of aquifer properties with depth. Finally, the optimal total depth of borehole to drill was estimated, and a map highlighting the spatial distribution of this total depth was created.

2.3.1. Elementary Statistical Analysis

The borehole parameters analyzed are: Total depth of borehole (Td); Saprolite thickness (St); Length of borehole below the base of saprolite (Lbs) and Instantaneous discharge (Qi) (air-lift flow rate at the end of development). Each parameter, which is in fact a statistical variable, was classified into classes and the frequency of each class was calculated. A comparative analysis of the parameter frequencies, based on lithology, was then performed.

2.3.2. Analysis of the vertical variation of aquifer properties

The geometric and hydrodynamic properties of the aquifer were highlighted. The analysis first focused on the distribution of inflows, according to the length of borehole below the base of the saprolites (Lbs).

Inflows are assumed to be associated with conductive fissure zones. Analyzing the distribution of inflows with depth could provide insights into the permeable zones of the aquifer. Secondly, the distribution of the cumulative percentage of linear discharges, as a function of the length below the base of the saprolites (Lbs), was studied. This step gave rise to the concepts of linear discharges, cumulative percentage of linear discharges, and average aquifer productivity.

2.3.2.1. Linear discharge

Linear discharge represents the instantaneous discharge per meter of rock formation crossed. For the study of aquifer properties, the linear discharge was preferred to the instantaneous one. The latter could be a biased variable because it can depend on the total depth of the well (Courtois et al., 2010). Indeed, the total depth of the well would be an arbitrary value, depending more on obtaining an adequate or desired discharge. This value therefore cannot reflect the intrinsic properties of the aquifer.

Linear discharge can be a function of the total depth of the well or can be defined relative to the length of well below the base of the saprolites. In this study, linear discharges were estimated relative to the well length below the base of the saprolites, using the expression:

$$q_l(l_i) = \frac{Q_i}{l_i}, i = 1, n \quad (1)$$

Where:

Q_i is the instantaneous discharge;

l_i is the length from the base of the saprolites;

q_i represents the linear discharge, referring to the length below the base of the saprolites;

i is the rank of the well;

n is the total number of wells.

2.3.2.2. Cumulative percentage of linear discharge

The cumulative percentage of linear discharge is highlighted through the following relation:

$$P_q(L) = \frac{\sum_{l=Lmin}^{l=L} q_i(l)}{\sum_{l=Lmin}^{l=Lmax} q_i(l)} \quad (2)$$

Where:

$P_q(L)$, denotes the cumulative percentage of linear discharge, whose length below the base of the saprolites is less than L (m).

Each linear discharge corresponds to a value of well length below the base of the saprolites L (m). The linear discharges are ranked according to increasing values of L (m). The cumulative percentages of linear discharges ($P_q(L)$) therefore vary from $P_q(Lmin) = 0\%$ to $P_q(Lmax) = 100\%$.

The curve linking each $P_q(L)$ to the corresponding well length below the base of the saprolites is produced (Figure 3). Analysis of this curve highlights the most transmissive zone of the aquifer. The latter is obtained through the portion of the curve that presents a linear trend and corresponds to the "Useful Thickness (L_u)" of the aquifer (Courtois et al., 2010) (Figure 2).

Figure 2: Curve of cumulative percentages of linear discharges for estimating aquifer fissured layer properties (after Courtois et al., 2010)

2.3.2.3. Average aquifer productivity

The average productivity relative to the L_u is determined according to the relations:

$$q_M(L_u) = \sum_{i=1}^{L_u} q_i(l)/j(L_u), \quad i = 1, n \quad (3)$$

$$Q_M(L_u) = q_M(L_u) \times L_u \quad (4)$$

L_u is the effective thickness of the fissured zone;

$q_M(L_u)$ is the average linear discharge, obtained with L_u ;

$j(L_u)$ is the number of wells corresponding to L_u ;

$Q_M(L_u)$ denotes the average discharge obtained with the L_u .

$Q_M(L_u)$ is the resulting mean discharge for theoretical wells that would intersect the whole useful thickness (L_u) of the fissured layer (Courtois et al., 2010).

2.3.3. Estimating the Optimal Drilling Depth

We define the optimal drilling depth as the depth that must be reached when drilling the borehole to ensure that the entire most transmissive zone of the aquifer is captured. The area beyond the optimal depth is a contingency zone.

The driller may encounter a conductive or non-conductive fracture there, and the risk of financial losses on the investment cost is higher.

184 At a given point, the optimal depth (Pop) corresponds to the useful length (Lu) increased by the thickness of the
185 saprolites.

$$P_{op} = Lu + St \quad (5)$$

186 To make Pop an integer, each value of Lu and St, which is a decimal number, was rounded up to the nearest whole
187 number.

188 The kriging method was used to create a map showing the spatial distribution of the optimal drilling depth.

189 3. Results and discussion

190 3.1. Results

191 3.1.1. Statistical distribution of well parameters

192 The results of the statistical study of borehole parameters are presented in Table 1 below.

193 **Table 1:** Statistical distribution of borehole parameter frequencies according to classes

Total depth of borehole (m)				
	25 -50	50 -75	75 -100	100 -120
MTR	38.42	44.63	15.81	1.13
Frequency (%)				
MGR	13.04	61.96	25	0
Frequency (%)				
MGDR	38.24	44.12	17.65	0
Frequency (%)				
Thickness of the saprolite (m)				
	0 - 25	25 -50	50 -75	75 - 85
MTR	80	20	0	0
Frequency (%)				
MGR	40.22	55.43	4.35	0
Frequency (%)				
MGDR	58.82	41.15	0	0
Frequency (%)				
Length of borehole below the base of saprolite (m)				
	0 - 35	35 -65	65 -95	95 - 125
MTR	35.80	50.57	13.07	0.57
Frequency (%)				
MGR	49.45	42.86	7.61	0
Frequency (%)				
MGDR	50	44.12	5.88	0
Frequency (%)				
Instantaneous discharge (m ³ /h)				
	0 - 2,5	2,5 - 5	5 - 10	10 - 20
MTR	50	22.08	19.48	8.44
Frequency (%)				
MGR	69.32	11.36	13.64	5.68
Frequency (%)				
MGDR	57.14	25	10.71	7.14
Frequency (%)				

194

195 **3.1.1.1. Total depth of boreholes (TD)**

196 All the boreholes in the database, carried out on each of the lithologies, have total depths (TDs) between 30 and 115
197 m. The interval 50 to 75 m has the highest frequencies, while the frequencies are almost zero on the interval 100 to
198 120 m, whatever the lithology. The TDs, between 50 and 75 m, represent 44.63 %, 61.96 % and 44.12 %, respectively,
199 on the MTR, MGR and MGDR. Following this same order of lithologies, the frequencies are 38.42 %, 13.04 % and 38.24 %, for the TDs vary between 25 and 50 m. Boreholes with TDs ranging from 50 to 100 m have
200 frequency estimates of 60.44 %, 86.96 %, and 61.77 %, on the MTR, MGR, and MGDR rocks, respectively.
201

202 Overall, the highest TDs are most frequently encountered first on the MGR, then on the MGDR, and then on the
203 MTR.

204 **3.1.1.2. Thickness of the saprolite (TS)**

205 Saprolite thickness range from 1.28 to 48.65 m on the MTR, from 3.08 to 72.05 m on the MGR and from 7.54 to
206 48.59 m on the MGDR. Boreholes with saprolite thicknesses less than 25 m represent 80 % on the MTR band, while
207 on the MGR and MGDR they occupy 40.22 % and 58.82 % respectively. Saprolite thicknesses between 25 and 50 m
208 occupy 20 %, 55.43 % and 41.15 % respectively on the MTR, MGR and MGDR. Beyond 50 m, the frequencies are
209 zero, except on the MGR, where the frequency is 4.35%.

210 The lowest saprolite thicknesses (≤ 25 m) have a greater occurrence on the MTR, then on MGDR and then on MGR.

211 **3.1.1.3. Length of borehole below the base of saprolite (Lbs)**

212 Length of boreholes below the base of saprolite (Lbs) less than 35 m represent 35.80 %, 49.45 %, and 50 %, respectively,
213 for the MTR, MGR, and MGDR rocks. In the same order, Lbs between 35 and 65 m represent 50.57 %, 42.86 %, and 44.12 %. Between 65 and 95 m, the frequencies are 13.07 %, 7.61 %, and 15.88 %, respectively. There
214 are virtually no Lbs exceeding 95 m.
215

216 The longest Lbs are slightly more common in the MTR than in the other two lithologies (MGR and MGDR). The
217 frequencies of the Lbs classes, on the latter two (MGR and MGDR) are significantly close.

218 **3.1.1.4. Instantaneous discharges (Qi)**

219 Instantaneous discharges (Qi) below 20 m³/h are statistically analyzed. On the MTR, eight (8) Qi values, including
220 one of 45 m³/h, are above 20 m³/h. Five (5) Qi values above 20 m³/h are noted, including one reaching 90 m³/h, on
221 the MGDR. Finally, on the MGR, only one (1) Qi value (21.6 m³/h) is above 20 m³/h.

222 Low Qi (2.5 m³/h) are more common. Their frequencies are 50 %, 69.32 %, and 57.14 %, respectively, on the MTR,
223 MGR, and MGDR. These Qi are most frequently observed on the MGR (69.32 %), while the MTR recorded the
224 lowest frequency (50 %). On the other hand, regarding average Qi (2.5 m³/h < Qi < 5 m³/h), the highest frequency is
225 noted on the MGDR (25 %) and the lowest is obtained on the MGR (11.36 m³/h). Qi values below 5 m³/h represent
226 72.08 %, 80.68 % and 82.14 %, respectively, on the MTR, MGR and MGDR.

227 Overall, we note that the highest Qi have a relatively higher occurrence on the MTR and lower occurrence on the
228 MGR.

229 **3.1.2. Properties of the Divo-Guitry hard rock aquifer**

230 **3.1.2.1. Vertical distribution of inflows and cumulative percentages of linear discharges**

231 a) Metatonalite Rock (MTR)

232 The distributions of inflows and cumulative percentages of linear discharges, as a function of length below the base
233 of the saprolites, in the case of MTR, are illustrated in Figure 3.

234 Inflows are observed between 0 and 90 m below the base of the saprolites (Figure 3a). However, these tend to
235 decrease with depth. This decrease with depth appears more marked after 50 m, and even more so, from 68 m,
236 below the base of the saprolites (see the dividing line in Figure 3a). The discharges associated with these water
237 inflows are mostly (75.30 %) less than 15 m³/h. Inflows with associated discharges greater than 5 m³/h (the most
238 variable flow rates) are predominant between 10 and 68 m below the base of the saprolites. There are several
239 significant discharges between 15 and 35 m³/h and one of 45 m³/h. This zone between 10 and 68 m is the zone
240 where the flow rates are the most variable (> 5 m³/h).

241 The curve of the variation of the cumulative percentages of linear discharges as a function of the length below the
242 base of the saprolites is presented in Figure 3b. This curve starts with 0 %, around 10 m. For its interpretation, it can
243 be split into three parts:

244 • the first part is between 0 and 4 %, with a relatively steep slope, which would reflect two hypotheses: either a low
245 density of conductive fissures, in the first meters below the base of the saprolites, or an uncertainty in the location of
246 the saprolite-fissured zone interface; this second hypothesis seems the most plausible;

247 • the curve adopts a gentle decrease, highlighted by the somewhat linear shape it follows, down to 88 % (or even a
248 little more), corresponding to 53.99 m, representing the useful length (L_u); this suggests a regular decrease in linear
249 discharges, which would mean that the number of conductive fissures would be steadily decreasing with depth; this
250 zone would contain the most variable instantaneous discharges and would be the most productive zone of the
251 aquifer;

252 • after the quasi-linear zone, the graph curves and thus seems to mark the rapid decrease in linear discharges with
253 depth; this part of the aquifer would correspond to the lowest part of the fissured zone and would be characterized
254 by a low density of conductive fissures.

Figure 3. Vertical distribution of the properties of the MTR aquifer: a) analysis with inflows; b) analysis with cumulative percentages.

The useful length (Lu) of 53.99 m (obtained at 88 %), below the base of the saprolites, appears to contain the highest density of conductive fissures. This Lu could be considered the horizon of the fissured layer, above the unweathered MTR.

To ensure optimum productivity, we suggest that boreholes drilled on the MTR necessarily reach 53.99 m below the base of the saprolites.

The average discharge obtained at this optimum depth of 53.99 m is 7.0 m³/h.

b) Biotite metagranite rock (MGR)

The distributions of inflow discharges and cumulative percentages of linear discharges, as a function of length below the base of the saprolites, for MGR, are presented in Figures 4a and 4b, respectively.

Figure 4. Vertical distribution of the properties of the MGR aquifer: a) analysis with water inflows; b) analysis with cumulative percentages.

Inflows are present between 0 and 65 m below the base of the saprolites (Figure 4a). However, their occurrence appears to decrease with depth. This is particularly noticeable after 46 to 47 m, below the base of the saprolites (see the demarcation line in Figure 4a). Most of the inflow discharges (83.43 %) are less than $5 \text{ m}^3/\text{h}$. An exceptional discharge of $21.6 \text{ m}^3/\text{h}$ is observed at the saprolite-fissured zone interface (0 m). The inflow discharges are more

275 variable between 10 and 46 m. Beyond 46 m, there are 3 boreholes with inflow discharges greater than 5 m³/h,
276 including one value reaching 20 m³/h.

277 The curve showing the evolution of cumulative percentages of linear discharges as a function of length below the
278 base of the saprolites shows a regular decrease (Figure 4b). It also highlights the three parts described above, in the
279 case of the MTR. The first part, between approximately 0 and 5 %, with a relatively steep slope, certainly reflects
280 the effect of uncertainty in the location of the saprolite-fissured zone interface. The second part takes on a quasi-
281 linear appearance up to 88.59 %, corresponding to 50.58 m, before ceasing. This suggests the regular decrease with
282 depth of conductive fissures and that fissures are denser in the first 50 meters below the base of the saprolites. When
283 drilling a borehole on MGR, reaching a depth of 50.58 m, below the base of the saprolites, which corresponds to the
284 useful length (Lu), could ensure optimal exploitation of the aquifer.

285 The average flow rate obtained with the useful length (Lu) of 50.58 m is 5.14 m³/h.

286 c) Biotite metagranodiorite rock (MGDR)

287 Figures 5a and 5b show, respectively, the distributions of inflow discharges and the cumulative percentages of linear
288 discharges, as a function of length from the base of the saprolites, in the case of MGDR.

289 The number of inflows decreases with depth, and this appears more pronounced after 30 m (see demarcation line in
290 Figure 5a), below the base of the saprolites (Figure 5a). 75 % of the water inflow rates are less than 5 m³/h. The
291 most variable discharges are in the first 30 meters, below the base of the saprolites. However, significant discharges
292 can be encountered beyond these 30 m. In fact, an exceptional discharge of 90 m³/h is highlighted, around 40 m,
293 below the base of the saprolites.

294 Like the other curves (Figures 3b and 4b), the curve in Figure 5b decreases and mainly shows three parts. The first
295 part starts from 0 to about 4 %, with a relatively steeper slope. As mentioned above (see the analysis on the MTR),
296 this steep slope could mean an uncertainty related to the positioning of the saprolite-fissured zone interface. The
297 second part (quasi-linear part) extends between 4 and 87 % and highlights the greatest density of conductive fissures
298 in the aquifer. This zone corresponds to the useful length (Lu) which is estimated at 36.93 m, below the base of the
299 saprolites. Within the quasi-linear zone, points indicating slope breaks (40.13% and 47.07%), which are relatively
300 less significant, are perceptible. Finally, the third part, which is located beyond 87 % (36.93 m), characterized by a
301 steep slope, indicates the lowest part of the fissured zone, resulting from its low density of conductive fissures. To
302 ensure optimum productivity, it would be desirable for boreholes drilled on MGDR to necessarily reach 36.93 m
303 below the base of the saprolites.

304 The average flow rate obtained with the Lu of 36.93 m is 8.30 m³/h.

Figure 5. Vertical distribution of the properties of the MGDR aquifer: a) analysis with inflows; b) analysis with cumulative percentages

3.1.3. Spatial distribution of optimal drilling depth

Optimal drilling depths range from 45 to 124 m. Figure 6 below highlights the spatial distribution of optimal drilling depths. The greatest values (from 89 to 100 m, or even more) are observed along the MGR belt, particularly between Gagnoa and Zikisso, and extend towards Lakota. Intermediate depths (67 to 88 m) are also more spread out across the MGR.

Figure 6. Spatial distribution of optimal drilling depths

These depths, ranging from 67 to 88 m, are noted on the MGDR and MTR belts, particularly in the northeastern part. The shallowest depths (45 to 66 m) are observed on the MGDR and MTR.

In the southern part, around Gbagbam and between Gbagbam and Guitry, the shallowest optimal depths (45 to 55 m) are present. They also extend towards Divo.

Overall, the spatial distribution of optimal drilling depths is guided by the spatial distribution of saprolite thicknesses.

3.2. Discussion

The borehole parameter values were divided into different classes, and the class sizes were subject to a comparative analysis, based on the geological formations. This study revealed the following:

- the greatest values of total borehole depths and saprolite thickness are more prevalent first on the MGR, then on the MGDR, and finally on the MTR;

- the greatest lengths of boreholes below the base of saprolite are slightly more prevalent on the MTR than on the other two lithologies (MGR and MGDR), which indicate substantially similar frequencies;

- the discharges range across the three lithologies is dominated by low discharges ($< 2.5 \text{ m}^3/\text{h}$); the highest flow rate values are more prevalent, first on the MTR, then on the MGDR, and finally on the MGR.

These observations would be characteristic of exploitation boreholes, carried out in the middle of the hard rocks of rural areas. Indeed, the cost of boreholes is determined by the near meters dug. Also, the total depth of the borehole, which includes the thickness of the saprolites and the length below the base of saprolites, is linked to achieving a high flow rate or the desired flow rate. Thus, for cost reasons, drilling is most often stopped as soon as the adequate flow rate is achieved. Flow rates in the middle of the hard rock are relatively modest and are generally sufficient for rural areas, where water needs are relatively lower. In the study area, the thickness of the saprolites, which are greater in the western part, in the localities of Zikisso and Lakota, decreases steadily towards the east (Géomines, 1982). Thus, depending on the arrangement of the geological formations, the order of decreasing importance of the thicknesses of the saprolites is as follows: MGR, MGDR and MTR (Tagnon, 2021).

This would explain the results obtained in this study and recalled above, in this section 3.2. Indeed, where the thickness of the saprolites is significant (MGR), there is a tendency to have large values of total borehole depth and where the thickness of the saprolites is small (MTR), the greatest lengths of borehole below the base of saprolites are frequent. Also, in these areas of small thicknesses of the saprolites (MTR), high flow rates also have a greater occurrence, certainly because the drillings extend over large lengths below the base of saprolites, thus capturing a relatively greater number of conductive fissures.

The analysis of the distributions of inflows and the cumulative percentages of linear discharges made it possible to highlight the geometric and hydrodynamic properties of the Divo-Guitry hard rock aquifer. These two approaches revealed similar information for some and complementary information for others. In terms of complementary information, we note a decrease with depth in the density of conductive fissures. This was highlighted by the decrease as a function of depth, in the number of inflows, on the one hand, and the decrease as a function of depth, in the cumulative percentages of linear discharges, on the other hand. Also, these two approaches revealed, in an almost similar way, for each lithology, the area of greatest density of conductive fissures, under the base of the saprolites. In the case of the MGR, this zone was identified at 47 m, below the base of the saprolites, with the approach involving inflows and at 50.58 m, with the approach of cumulative percentages of linear discharges. Regarding the complementarity aspect, the results, the approach which involves inflows made it possible to note the presence of the latter from the first meters below the base of the saprolites. This means that conductive fissures would be present from the first meters below the base of the saprolites. This result is not perceptible with the method using the cumulative percentages of linear discharges. Indeed, this method, in its execution, uses the lengths below the base of the saprolites, reached by the boreholes. In the database, the minimum values taken by the latter are

around 10 m. This is the reason why the curves involving the cumulative percentages of linear discharges (Figures 3b, 4b and 5b), start around 10 m, below the base of the saprolites. They therefore do not provide information on the presence or not of conductive fissures in the first meters below the base of the saprolites. The complementarity and similarity of the information obtained with the two approaches justify their concomitant use in highlighting the geometric and hydrodynamic properties of fractured basement aquifers.

The approaches developed in this study to characterize the properties of the Divo-Guitry aquifer showed a decrease in the density of conductive fissures with depth. This observation was also made by several authors including Courtois *et al.* (2010), in Burkina Faso, Aoulou *et al.* (2021), Kouamé *et al.* (2021) and Bouatrin *et al.* (2022), in Côte d'Ivoire. The useful lengths (Lu) obtained are 53.99 m, 50.58 m and 36.93 m, respectively on the MTR, MGR and MGDR. Lu on the MTR and Lu on the MGR are practically in the same order. However, the Lu on the MTR is greater, by about 4 m, than the Lu on the MGR. This difference would be because the greatest basement lengths reached by the boreholes are more numerous on the MTR than on the MGR. The useful length (Lu) obtained on the MGDR (36.93 m) is relatively lower. However, the average flow rate corresponding to this useful length, which is estimated at 8.30 m³/h, is greater than the average flow rates noted on the other two lithologies (7 m³/h for the MTR and 5.14 m³/h for the MGR). These results would be linked to the particularities of the weathered process on the MGDR rock, at the local level.

Also, it should be noted that the number of boreholes used for processing on the MGDR is relatively low. This could introduce biases into the results obtained. In western Côte d'Ivoire, Aoulou *et al.* (2021) obtained a Lu equal to 43 m, on biotite granodiorites and biotite metagranodiorites. The difference with our study is that our analysis only takes place on the biotite metagranodiorite (MGDR) lithology. Kouamé *et al.* (2021) obtained a Lu of 40 m, in the Tchologo region and Bouatrin *et al.* (2022) noted an average Lu of 45 m, in the Marahoué watershed. The results obtained by these authors concern a set of crystalline lithologies. On the contrary, each Lu that we obtained in our study concerns a single lithology. In Burkina Faso, Courtois *et al.* (2010) noted that conductive fissures have an optimal density between 8 and 25 m below the base of saprolites, on porphyritic biotite granites. The extent of conductive fissures is small compared to those observed in our study. This difference would be related to the local particularities of the weathering process, which would be deeper in the relatively more humid areas of Côte d'Ivoire.

Beyond the demarcation line highlighted in Figures 3a, 4a and 5a, the presence of inflows in the boreholes is noted. In some cases, the discharges of these inflows are considerable. This suggests that when drilling beyond the demarcation line or beyond the useful length (Lu), it is possible to encounter open and hydraulically active fractures, which could provide significant, even exceptional, discharges. However, the probability of encountering these hydraulically active fractures is reduced beyond the demarcation line or the useful length (Lu).

Conclusion

Statistical analysis of drilling parameters revealed that these are characteristics of exploitation boreholes in hard rock zones, particularly in rural areas. Indeed, high total depth values are more common in areas with the greatest saprolite thicknesses, while drilled bedrock thicknesses are relatively greater in areas with thin saprolite thicknesses. Also, the lowest flow rates (2.5 m³/h) are the most frequent. Analysis of geometric and hydrodynamic properties showed that inflows are present from the first few meters below the base of the saprolites and that the density of conductive fissures decreases with depth. The most variable inflow discharges (> 5 m³/h) are noted between 10 and 68 m, 10 and 46 m and at 30 m, under the base of the saprolites, respectively, on the MTR, MGR and MGDR. Following this same order, the calculated useful lengths (Lu), are respectively 53.99 m, 50.58 m and 36.93 m. To these Lu, correspond respectively, the average instantaneous discharges of 7 m³/h, 5.14 m³/h and 8.30 m³/h.
