Key words:-

Class III malocclusion, mandibular prognathism, maxillary protraction, growth modification, orthodontic camouflage, orthognathic surgery, maxillary skeletal expansion

Abstract

Class III malocclusion is a multifactorial dentofacial deformity characterised by an abnormal sagittal relationship between the maxilla and mandible, most commonly manifesting as maxillary retrognathia, mandibular prognathism, or a combination of both. Its prevalence varies markedly across populations, from below two percent in several Indian and Northern European cohorts to over fifteen percent in East and Southeast Asian groups, reflecting an interplay of genetic, environmental, and functional determinants. Because the disorder spans dental, skeletal, and functional dimensions, accurate differential diagnosis — distinguishing true skeletal Class III from dentoalveolar compensation and pseudo (functional) Class III — underpins rational treatment planning. This review synthesises the etiology, classification, epidemiology, and stepwise management of Class III malocclusion across the growth continuum. In growing patients, correction of simple crossbites, functional appliance therapy, chin-cup treatment, and maxillary protraction with or without rapid maxillary expansion remain central to interceptive management, with the Growth Treatment Response Vector offering a means of predicting subsequent mandibular growth and guiding the decision between camouflage and surgery.

camouflage for mild-to-moderate skeletal discrepancy and combined orthodontic–orthognathic surgery for severe disharmony, increasingly guided by three-dimensional imaging and virtual surgical planning. A structured, age- and severity-stratified approach, summarised here through diagnostic and treatment algorithms, remains essential to stable functional and esthetic outcomes.

Introduction:-

Class III malocclusion is a complex dentofacial deformity defined by an abnormal anteroposterior relationship between the maxilla and mandible, commonly presenting as mandibular prognathism, maxillary deficiency, or a combination of both components. Although Edward Angle's original classification was based purely on molar relationship, the disorder is now recognised to involve both dental and skeletal discrepancies, frequently accompanied by anterior crossbite and reversed overjet [1,2]. The condition is often readily apparent from the characteristic concave facial profile, prominent chin, and deficient midface, and can carry substantial functional and psychosocial consequences. A thorough family history, together with clinical assessment of the facial profile in natural head position and cephalometric analysis, is essential to determine whether the discrepancy originates in the maxilla, the mandible, or the cranial base [3]. A central diagnostic challenge is distinguishing true skeletal Class III malocclusion from pseudo (functional) Class III, in which occlusal interference in centric relation causes an anterior mandibular shift into centric occlusion; elimination of this interference typically restores a Class I relationship, whereas persistence of the Class III molar relationship indicates a true or compensated skeletal problem [2,6].

Class III malocclusion is widely regarded as one of the most challenging malocclusions to diagnose and treat, owing to its variable presentation and unpredictable growth trajectory. Early identification is critical, since interceptive treatment during growth can favourably influence dentofacial development and, in some cases, reduce or eliminate the eventual need for orthognathic surgery. This review consolidates the etiological, diagnostic, and management literature on Class III malocclusion into a single, age-stratified framework spanning interceptive orthopaedic treatment, contemporary fixed and removable appliances, maxillary skeletal expansion in adults, combined orthodontic–orthognathic surgery, orthodontic camouflage, and digital treatment planning.

Etiology:-

The etiology of Class III malocclusion is multifactorial, arising from an interaction of genetic, environmental, and functional influences on craniofacial growth rather than from any single causative factor.

Genetic and hereditary factors:-

A strong familial tendency is frequently observed, with a polygenic inheritance pattern most commonly proposed, although autosomal dominant and recessive modes have also been suggested. The “Habsburg jaw” — the pronounced mandibular prognathism and everted lower lip seen across generations of the Habsburg royal family, exemplified by Charles II of Spain — remains the classic teaching example of hereditary skeletal Class III malocclusion, attributed in part to consanguineous inheritance [27–36].

Certain syndromes, including Down syndrome and Crouzon syndrome, may also present with Class III features:-

- Environmental and congenital factors: cleft lip/palate and other congenital anomalies can restrict midfacial growth and produce anterior crossbite; congenital absence of maxillary teeth may similarly disrupt normal occlusal development.
- Systemic and respiratory factors: pituitary disorders causing gigantism or acromegaly can drive excessive mandibular growth, while enlarged tonsils/adenoids and chronic nasal obstruction alter tongue posture and mandibular positioning.
- Local dental and functional factors: premature loss of primary teeth, ectopic eruption, tongue thrusting, and habitual forward mandibular posturing can each precipitate a Class III relationship.
- Epigenetic factors: environmentally driven modification of gene expression, without change to the underlying DNA sequence, is increasingly recognised as an additional contributor to mandibular growth and craniofacial development.

Overall, Class III malocclusion is best conceptualised as a multifactorial condition in which the relative contribution of each determinant varies between individuals, necessitating individualised diagnosis and treatment planning.

Classification:-

Because Class III malocclusion presents with considerable variability in its skeletal, dental, and functional components, several complementary classification systems are used in clinical practice (Fig. 1).

- By etiology: skeletal Class III (true jaw-base discrepancy), dental Class III (normal skeletal bases with compensatory tooth position), and functional/pseudo Class III (forward mandibular positioning due to occlusal interference).
- By skeletal component: maxillary deficiency, mandibular prognathism, or a combined discrepancy, each carrying different treatment implications.
- By severity: mild (predominantly dentoalveolar, amenable to orthodontics alone), moderate (combined orthopaedic and orthodontic need), and severe (typically requiring orthognathic surgery after growth completion).
- Tweed's classification: Category A corresponds to pseudo Class III malocclusion with a functionally displaced but structurally normal mandible; Category B denotes true skeletal Class III arising from mandibular prognathism or maxillary deficiency.
- By growth pattern: a forward (horizontal) rotational growth pattern tends to accentuate the Class III relationship, whereas a vertical growth tendency, through downward-backward mandibular rotation, may reduce its apparent severity [4].

Fig. 1. Classification schema of Class III malocclusion by etiology, skeletal component, and severity.

Epidemiology:-

A systematic review and meta-analysis of Class III malocclusion reported a global prevalence ranging widely from 0% to 26.7%, a variation attributable to differences in sample characteristics, age groups, and diagnostic methodology [7]. Prevalence is consistently highest among East and Southeast Asian populations and lowest among Indian and several Northern European cohorts (Table 1) [7,8,9–24].

Table 1. Reported prevalence of Class III malocclusion by region and population.

Region / population	Prevalence (%)
Global (all populations)	0–26.7
Southeast Asian	15.80
Chinese	15.69
Malaysian	16.59
Japanese	2.3–14
Korean	9–19
Taiwanese	1.65
Indian (children, 5–15 y)	0–4.76 (lowest reported: 1.19)
Middle Eastern (overall)	10.18
Iranian	15.20
Turkish	10.30–11.5
Egyptian	4–11.38
African (overall)	4.59
Tanzanian	1.81–19.72
Nigerian	1.22–16.8
European (overall)	2–6 (mean $\approx$ 4.88)
UK / Scandinavian	3–5
American (overall)	5–9.1
Mexican American	8.30
Latino American	9.10
Saudi Arabian	9.40
Syrian	14.0

This wide variation, both within and between populations, underscores the need for standardised diagnostic criteria when comparing Class III prevalence data, and suggests that ethnicity should be factored into risk assessment and counselling of patients and families.

Diagnostic Assessment and Components:-

Class III malocclusion represents a three-dimensional imbalance between maxillary and mandibular growth, combined with variable dentoalveolar and soft-tissue compensation. Park and Baik classified skeletal Class III into three types based on maxillary position: Type A (normal maxilla, prognathic mandible), Type B (excessive growth of both jaws with relatively greater mandibular growth), and Type C (maxillary hypoplasia with an obtuse nasolabial angle), the last of which is generally the most amenable to orthodontic camouflage [50]. Reduced anterior and posterior cranial base lengths, a diminished saddle angle, and an increased gonial angle have each been associated with a more anteriorly positioned glenoid fossa and, consequently, a Class III skeletal pattern [51–53].

Differential diagnosis follows a stepwise approach: family history of mandibular prognathism or crossbite; assessment of any functional shift between centric relation and centric occlusion; clinical evaluation of the facial profile in natural head position; and lateral cephalometric analysis using ANB, Wits appraisal, and related linear measurements (Fig. 2) [6,60–65]. The Wits appraisal has been identified as the most influential single parameter in

the decision between orthodontic camouflage and surgery: values between 0 and -5 mm are generally amenable to camouflage with a facemask or chin cup, whereas values between -4 and -12 mm warrant further growth-response analysis before a definitive decision is made [66,67].

Fig. 2. Simplified diagnostic algorithm for differentiating skeletal, dental, and functional (pseudo) Class III malocclusion.

Growth prediction and the Growth Treatment Response Vector (GTRV):-

Because the long-term stability of orthopaedic treatment depends heavily on residual mandibular growth, several methods have been proposed to predict this growth from a single cephalogram, most notably Björk's seven structural signs of mandibular growth rotation [79]. Reported long-term success rates for orthopaedic treatment of skeletal Class III malocclusion range from 50.0% to 71.4%, though comparability across studies is limited by differing success criteria [77,78,80–83]. Ngan's Growth Treatment Response Vector (GTRV) analysis instead uses serial post-treatment cephalograms to compare horizontal growth at point A (maxilla) and point B (mandible) relative to the occlusal plane (Fig. 4) [84–86]. For individuals aged 6–16 years with a normal growth pattern, the GTRV averages 0.77; camouflage after early interceptive treatment succeeds within a GTRV range of 0.33–0.88 (mean 0.45), whereas a ratio below 0.38 predicts an unfavourable outcome and forewarns of a probable future surgical requirement.

Fig. 4. Schematic concept of the Growth Treatment Response Vector (GTRV) used to predict maxillary versus mandibular growth after early interceptive treatment.

Turpin proposed a set of positive and negative clinical indicators to guide the decision of whether to intercept a developing Class III malocclusion or defer treatment until growth completion (Table 2) [99], and a summary of optimum intervention timing and indicators is presented in Table 3 [91–93].

Table 2. Turpin's positive and negative factors for decision-making in developing Class III malocclusion [99].

Positive factors (favour early interception)	Negative factors (favour delaying treatment)
Convergent facial type	Divergent facial type
Anteroposterior functional shift present	No anteroposterior functional shift
Symmetrical condylar growth	Asymmetrical condylar growth
Young patient with remaining growth; mild skeletal disharmony	Growth largely completed; severe skeletal disharmony
Good cooperation expected	Poor cooperation expected
No familial mandibular prognathism	Established familial pattern of prognathism
Good facial esthetics	Poor facial esthetics

Table 3. Optimum timing of intervention and treatment indicators for Class III malocclusion with or without constricted maxilla [91–93].

Optimum timing	Main indicators	Typical modality
Pubertal growth phase (up to ~8 y in girls; ~9 y in boys)	Chronological age; phase of dentition (up to mixed dentition); cervical vertebral maturation (CS1–CS2); hand-wrist maturation (SMI 1–SMI 2)	Protraction facemask, with or without maxillary expansion

Management of the Growing Class III Patient:-

Treatment of a developing Class III malocclusion is guided primarily by dentition stage and by whether the discrepancy is dental, functional, or skeletal in origin (Fig. 3). Simple dentoalveolar anterior crossbite can be corrected with a removable inclined plane, a modified inclined plane, an active Hawley appliance with a Z-spring, or a fixed “2×4” appliance, most of which achieve correction within three to six weeks to six months depending on the appliance and the degree of overbite/proclination present. Growth modification of the skeletal pattern in growing patients is achieved chiefly through functional appliances (Fränkel functional regulator III, reverse twin-block), chin-cup therapy, protraction facemask, and, more recently, bone-anchored appliances. Current evidence indicates that functional appliances act principally through dentoalveolar rather than skeletal change, proclining the upper incisors and retroclining the lower incisors, with the FR III restricting mandibular growth without materially stimulating maxillary advancement [108–111]. Chin-cup therapy redirects, rather than restrains, mandibular growth by inducing a backward mandibular rotation, and should generally be continued until growth completion, since discontinuation before this point allows the normal growth pattern to re-establish itself [112–115].

Protraction facemask (reverse headgear) remains the most widely used interceptive tool for developing skeletal Class III malocclusion with maxillary deficiency, applying 400–450 g of force per side for 12–14 hours daily over 6–9 months, typically combined with rapid maxillary expansion when transverse constriction coexists [116–118]. In a controlled clinical trial, facemask therapy achieved reverse-overjet correction in 70% of treated patients with a mean overjet gain of 4 mm and a 2.6° improvement in ANB relative to untreated controls; at six-year follow-up, only 36% of the facemask group required orthognathic surgery compared with 66% of controls [119,120]. A 2017 evidence-based review similarly concluded that facemask therapy produces moderate-quality evidence of short-term skeletal and dental benefit [121]. Bone-anchored maxillary protraction (BAMP) appliances, which apply Class III elastics between miniplates placed in the infrazygomatic crest and the mandibular symphysis, avoid the unwanted dentoalveolar side effects of tooth-borne protraction — buccal molar tipping, arch-length loss, and anterior crowding. Initial studies report an average of 4 mm of skeletal and soft-tissue maxillary advancement with negligible incisor or vertical change, and BAMP now extends interceptive treatment to slightly older patients (from around 11 years) in whom maxillary bone quality is adequate for miniplate placement [122–124].

Fig. 3. Age-related treatment algorithm for Class III malocclusion across the growth continuum.
Table 4. Summary of the contemporary appliance armamentarium for early correction of Class III malocclusion.

Appliance	Primary indication / dentition	Mechanism	Typical duration
Removable appliance with Z-spring ± posterior bite plate	Anterior dental crossbite; primary/early mixed dentition	Labial tipping of maxillary incisors; disclusion via bite plate	3–6 months
Lower inclined bite plane (Catlan's appliance)	Deep-bite anterior crossbite with limited posterior eruption	Guides maxillary incisors labially via cemented acrylic ramp	1–3 months
Fränkel functional regulator III (FR III)	Mild skeletal Class III with maxillary retrusion, no prognathism	Vestibular shields relieve restrictive muscle forces on maxilla	~1 year
Tooth-/mucosa-borne reverse-pull headgear (protraction facemask)	Skeletal maxillary deficiency; deciduous–early mixed dentition	Extraoral protraction of maxilla via intraoral splint and elastics	~1 year
Bone-borne reverse-pull headgear / BAMP	Skeletal maxillary deficiency, older children/adolescents	Direct skeletal protraction via titanium miniplates	~1 year
“2×4” fixed appliance	Dental crossbite with rotation/spacing; mixed dentition	Light continuous force via partial fixed appliance	~6 months
Transmission straight-wire appliance	Mild–moderate skeletal/dental Class III; permanent dentition	Light-force Class III elastics with staged archwire mechanics	Case-dependent
Clear aligners / lingual appliance	Esthetically motivated patients; mild–moderate cases	Sequential aligner or lingual-bracket tooth movement ± elastics/TADs	Case-dependent

Maxillary Skeletal Expansion for Transverse Deficiency in Adults:-

Transverse maxillary deficiency in the skeletally mature patient has traditionally required either tooth-borne rapid maxillary expansion (RME, e.g. Hyrax/Haas appliances) — which produces significant dentoalveolar tipping, buccal root resorption, and relapse once the mid-palatal suture has interdigitated — or surgically assisted expansion. The maxillary skeletal expander (MSE), anchored directly to the palatal vault by mini-screws, and the hybrid tooth-bone-borne miniscrew-assisted rapid palatal expander (MARPE), were developed to apply expansion forces directly to the basal bone while minimising dentoalveolar side effects.

Following early bone-borne designs, successive modifications have repositioned the miniscrews more posteriorly, closer to the junction of the hard and soft palate, to overcome the greater resistance to suture opening offered by the pterygoid plates and to achieve a more parallel, rather than wedge-shaped, opening of the mid-palatal suture. Reported success rates for MARPE in adult and late-adolescent cohorts range from roughly 84% to 87%, with craniofacial structural resistance and variability in suture calcification implicated in the minority of failures. Commonly used activation protocols apply approximately 0.2 mm per turn, most often at a rate of two turns daily (0.4–0.5 mm/day), although slower (alternate-day) and more rapid (three-turn) protocols have also been described to balance expansion rate against tissue tolerance. Adequate case selection — including CBCT-guided assessment of miniscrew positioning to avoid the nasopalatal canal, salivary structures, and molar root apices — remains central to minimising complications.

Combined Orthodontic–Orthognathic Surgical Management:-

Severe skeletal Class III malocclusion in the non-growing patient generally cannot be resolved through dentoalveolar compensation alone, and combined orthodontic–orthognathic treatment remains the definitive

approach. Surgical correction typically involves mandibular setback, maxillary advancement, or a combination of both; mandibular clockwise or counterclockwise rotation can be used to modify chin projection and lower facial height as part of the same procedure. Bilateral sagittal split osteotomy (BSSO) of the mandible and Le Fort I osteotomy of the maxilla, each with rigid internal fixation, are the most widely used procedures, and genioplasty is frequently required once the other planned osteotomies have altered the relative prominence of the chin.

The following illustrative case — a 17-year-9-month-old female with a concave profile, 5 mm negative overjet, bilateral Class III molar and canine relationships, and a constricted maxillary arch — was managed with a segmental Le Fort I osteotomy (expansion, advancement, and anterior impaction) combined with BSSO for counterclockwise mandibular rotation and genioplasty for pogonion advancement, following 11 months of presurgical orthodontic preparation. Table 5 summarises the pre-treatment, post-surgical, and 7-year follow-up cephalometric findings, which demonstrate long-term stability of the correction.

Table 5. Illustrative pre-treatment, post-surgical, and 7-year follow-up cephalometric measurements for a combined orthodontic–orthognathic Class III case.

Cephalometric variable	Pre-treatment	Post-surgical	7-year follow-up
SNA (°)	88.7	89.6	89.9
SNB (°)	87.9	88.3	90.0
ANB (°)	0.8	1.3	−0.1
SN–GoGn (°)	34.7	30.5	29.9
1.NA (°) — maxillary incisor to NA	23.8	27.3	28.8
1.NB (°) — mandibular incisor to NB	29.6	22.9	24.0
Interincisal angle (°)	125.8	128.0	126.7

Consistent with the wider literature, maxillary expansion was the least stable component of the surgical movement, while rigid internal fixation contributed to overall stability by permitting immediate function and reducing reliance on maxillomandibular fixation. No clinically significant skeletal relapse was observed at the 7-year review, supporting the durability of a single-stage segmental Le Fort I plus BSSO approach when appropriately planned.

Orthodontic Camouflage:-

Orthodontic camouflage aims to correct dental relationships and mask an underlying mild-to-moderate skeletal discrepancy without altering the jaw bases, and is indicated when growth is largely complete, the facial profile remains acceptable, and the patient either declines or does not require surgery. Camouflage relies on dentoalveolar compensation — proclination of the maxillary incisors and retroclination of the mandibular incisors — to establish a positive overjet despite the underlying skeletal Class III base. Extraction of mandibular premolars (most commonly upper second and lower first premolars) is the most frequent camouflage strategy, permitting retraction of the lower incisors and correction of negative overjet; Class III elastics and temporary anchorage devices (TADs) provide additional anchorage control, although elastics carry a risk of posterior extrusion and increased vertical dimension. Camouflage cannot correct the underlying skeletal discrepancy and is limited by the extent of dentoalveolar compensation achievable without compromising periodontal support or facial esthetics; stability is generally better in non-growing patients and depends on rigorous retention. Table 6 summarises the principal factors distinguishing candidates for camouflage from those requiring surgical correction.

Table 6. Camouflage versus orthognathic surgery: key distinguishing factors.

Factor	Camouflage	Surgery
Skeletal discrepancy	Mild–moderate	Severe
Facial profile	Acceptable	Poor esthetics / marked concavity

Factor	Camouflage	Surgery
Correction achieved	Dental (dentoalveolar) only	Skeletal (definitive) correction
Invasiveness	Less invasive	More invasive, requires surgical planning
Growth status	Growth largely complete preferred	Growth complete (or planned post-growth)

Digital Diagnosis and Three-Dimensional Treatment Planning:-

Advances in three-dimensional imaging have substantially improved the diagnosis and surgical planning of Class III malocclusion. Cone-beam computed tomography (CBCT) enables three-dimensional reconstruction of hard-tissue anatomy with reduced radiation dose relative to conventional CT, while three-dimensional photogrammetry captures the overlying soft-tissue envelope. Surgical planning software allows virtual cephalometric analysis, simulated repositioning of osteotomy segments, and prediction of the resulting soft-tissue profile, supporting more informed patient counselling. Computer-aided design/manufacturing and rapid prototyping (stereolithographic models, surgical splints, and cutting guides) further increase planning precision, and one comparative report found that digital planning reduced orthognathic treatment-planning time by 91% relative to conventional methods. Surface mapping and elliptical Fourier descriptors extend this quantitative approach to complex craniofacial asymmetry and syndromic cases. The principal limitations of these technologies remain cost and accessibility, but their incorporation into routine planning is likely to continue expanding as equipment and software become more widely available.

Conclusion:-

Management of Class III malocclusion remains one of the most demanding areas of orthodontic practice because of its multifactorial etiology, variable clinical presentation, and unpredictable growth trajectory. Accurate early diagnosis — distinguishing maxillary deficiency, mandibular prognathism, and functional mandibular shift — is central to selecting the appropriate treatment modality. In growing patients, interceptive and orthopaedic approaches, particularly maxillary protraction with or without rapid maxillary expansion, remain the cornerstone of management, contingent on patient compliance and correct timing. Once growth modification is no longer effective, treatment options narrow to orthodontic camouflage, which offers satisfactory but non-definitive correction in mild-to-moderate cases, or orthognathic surgery, which provides definitive skeletal correction in severe cases at the cost of greater invasiveness and the need for multidisciplinary coordination. Bone-anchored protraction and miniscrew-assisted maxillary expansion have extended orthopaedic options into later adolescence and adulthood, while three-dimensional imaging and virtual surgical planning continue to refine diagnostic precision and surgical predictability. Ultimately, the choice of treatment must be individualised according to the severity of the skeletal discrepancy, growth status, soft-tissue profile, and patient expectations, with long-term retention and follow-up remaining essential to a stable outcome.
